1 Introduction and Overview

This report presents a complete formalization, computational verification, figure reproduction, and generalization study of the paper "Error-Correction Transitions in Finite-Depth Quantum Channels" by Sauliere, Lami, Ribeiro, De Luca, and De Nardis [1]. The paper studies how random one-dimensional brickwall quantum circuits of depth t encoding $k = rN$ logical qudits into N physical qudits exhibit error-correction phase transitions governed by random-matrix (RM) universality.

1.1 Methodology

The formalization was carried out using the **Adversarial Proof Framework** (`af`), a command-line tool for collaborative construction of natural-language mathematical proofs with adversarial verification. The workflow proceeded as follows:

1. **Download**: Paper PDF and TEX source obtained from arXiv.
2. **Initialization**: `af init` created a proof workspace with the paper's main conjecture.
3. **Definitions**: Eight key mathematical objects defined via `af def-add`.
4. **Proof structure**: Root node refined into 5 sections (27 nodes total) via `af refine`.
5. **Ground truth**: All 13 key equations verified by string match against the local TEX source.
6. **Adversarial verification**: A verifier agent claimed, checked, and accepted all 27 nodes.
7. **Computational verification**: Independent Python script confirmed all analytical formulas.
8. **Figure reproduction**: All 5 numerical figures reproduced using the 1D effective model.
9. **Generalizations**: Six extensions explored beyond the paper's scope.

2 The Proof Tree

The complete proof tree, exported via `af export -format latex`, is presented below. Every node has been independently verified by the adversarial verifier agent against the ground-truth TEX source.

2.1 Root conjecture

Node 1 validated

For a 1D random brickwall quantum circuit of depth t encoding $k = rN$ logical qudits into N physical qudits with local noise channels, the coherent information I_c exhibits an error-correction phase transition governed by random-matrix universality at infinite depth. In **Setup I** (noiseless encoding + noise after), the Hashing bound $H_2 = g_{s,s} - g_{s,e} \leq 1 - r$ determines the critical noise rate, and finite-depth corrections scale as $Ne^{-2t/\tau}$ crossing over to $e^{-t/\tau}$. In **Setup II** (noisy encoding), the circuit fidelity parameter $f_2 = -(2/N)\log_d \tilde{F}$ replaces the Hashing bound with critical value $[f_2]_{\text{crit}} = (1-r)(1+g_{s,e})$, and finite-depth corrections scale as $O(1/t)$. Both setups reduce to 2D Ising-like statistical mechanics models via Weingarten calculus on replicated permutation degrees of freedom.

The root [Node 1] is decomposed into five child nodes covering the full argument.

2.2 Node 1.1: Background and framework

Node 1.1 validated

The coherent information $I_c(\Lambda) = S(\rho_B) - S(\rho_{RB})$ for a random encoding channel Λ mapping $k = rN$ logical qudits to N physical qudits can be computed via annealed 2nd-Rényi: $I_c = -\log_d \mathbb{E}_U[\mathrm{Tr}(\rho_B^2)] + \log_d \mathbb{E}_U[\mathrm{Tr}(\rho_{RB}^2)]$. Using Weingarten calculus, the Haar-averaged replicated circuit maps to permutation operators $\sigma \in S_2$ with noisy overlap matrix $\tilde{G}(d, \mathcal{N})$.

This section is supported by four leaf nodes:

Node 1.1.1 validated

DEF: Coherent information $I_c(\Lambda) = S(\rho_B) - S(\rho_{RB})$ where $\rho_{RB} = (1_R \otimes \Lambda)(|\phi_+\rangle\langle\phi_+|^{\otimes k} \otimes |0\rangle\langle 0|^{\otimes(N-k)})$.
Ground truth: `main.tex` line 134 contains `Ic(\Lambda)=S(\rho_{B})-S(\rho_{RB})`. **Verified.**

Node 1.1.2 validated

STEP: Replace von Neumann entropy S with 2nd Rényi $S_2(\rho) = -\log \mathrm{Tr}(\rho^2)$, and take annealed average over circuit realizations U, yielding $I_c = -\log_d \mathbb{E}_U[\mathrm{Tr}(\rho_B^2)] + \log_d \mathbb{E}_U[\mathrm{Tr}(\rho_{RB}^2)]$.
Ground truth: `main.tex` line 141 matches with `nreplicas=2`. **Verified.**

Node 1.1.3 validated

STEP: Apply Weingarten calculus for Haar(q):

$$\mathbb{E}_{U\sim\mathrm{Haar}(q)}\left[(U \otimes U^*)^{\otimes 2}\right] = \sum_{\pi,\sigma\in S_2} \mathrm{Wg}_{\pi,\sigma}(q)\, |\pi\rangle\rangle\langle\langle\sigma|. \tag{1}$$

The Gram matrix is $G_{\pi,\sigma}(q) = \langle\langle\pi|\sigma\rangle\rangle$ with $G = \left(\begin{smallmatrix} q^2 & q \\ q & q^2 \end{smallmatrix}\right)$, and $\mathrm{Wg} = G^{-1}$.
Ground truth: `main.tex` line 146. **Verified.**

Node 1.1.4 validated

STEP: Define noisy overlap $[\tilde{G}(q,\mathcal{N})]_{\pi,\sigma} := \langle\!\langle \pi|\mathcal{N}^{\otimes 2}|\sigma\rangle\!\rangle$. For depolarizing $\mathcal{N}(\rho) = (1-\gamma)\rho + \gamma 1/d$:

$$\tilde{G}(d,\mathcal{N}) = \begin{pmatrix} d^2 & d \\ d & 1+(d^2-1)(1-\gamma)^2 \end{pmatrix}. \tag{2}$$

Ground truth: `main.tex` lines 158–160. **Verified.**

2.3 Node 1.2: Setup I — Random-matrix prediction

Node 1.2 validated

For global Haar U, the averaged purities are $\mathbb{E}_U \operatorname{Tr}(\rho_B^2) = d^{-(g_{s,e}+1)N} + d^{-(g_{s,s}+r)N}$ and $\mathbb{E}_U \operatorname{Tr}(\rho_{RB}^2) = d^{-(g_{s,e}+1+r)N} + d^{-g_{s,s}N}$, giving $I_c/N = \min(g_{s,e}+1, g_{s,s}+r) - \min(g_{s,e}+1+r, g_{s,s})$. The Hashing bound $H_2 = g_{s,s} - g_{s,e} \leq 1-r$ determines the error-correction transition.

The derivation proceeds through four steps:

Node 1.2.1 validated

STEP: Start from the statistical-mechanical model Eq. (6): $\mathbb{E}_U \operatorname{Tr}\left(\rho_{B/RB}^2\right) = \langle\!\langle v_0|\mathbb{E}_U[(U\otimes U^*)^{\otimes 2}]|v_{B/RB}\rangle\!\rangle \otimes |0,0\rangle^{\otimes 2}$. For global Haar U, apply Eq. (1) to get two sums over S_2. In the large-N limit, only $\sigma = \pi = e$ and $\sigma = \pi = s$ contribute. The boundary vectors are $\langle\!\langle v_0| = \langle\!\langle s|\mathcal{N}^{\otimes 2}$ (top/noise), $|v_B\rangle\!\rangle = d^{-2k}|e\rangle\!\rangle$ and $|v_{RB}\rangle\!\rangle = d^{-2k}|s\rangle\!\rangle$ (bottom).

Node 1.2.2 validated

STEP: Evaluate boundary overlaps. For B-purity: $\langle\!\langle e|v_B\rangle\!\rangle = 1$, $\langle\!\langle s|v_B\rangle\!\rangle = d^{-k}$. For RB-purity: $\langle\!\langle e|v_{RB}\rangle\!\rangle = d^{-k}$, $\langle\!\langle s|v_{RB}\rangle\!\rangle = 1$. Combined with $\tilde{G}^N_{s,\pi}$ factors from noise, this yields Eq. (7):

$$\mathbb{E}_U \operatorname{Tr}\left(\rho_{B/RB}^2\right) = d^{-2N}\left(\tilde{G}^N_{s,e}\langle\!\langle e|v\rangle\!\rangle + \tilde{G}^N_{s,s}\langle\!\langle s|v\rangle\!\rangle\right). \tag{3}$$

Node 1.2.3 validated

STEP: Using $g_{\pi,\sigma} = \log_d G_{\pi,\sigma} - \log_d \tilde{G}_{\pi,\sigma}$ and $k = rN$, simplify to the RM purities:

$$\mathbb{E}_U \operatorname{Tr}(\rho_B^2) = d^{-(g_{s,e}+1)N} + d^{-(g_{s,s}+r)N}, \tag{4}$$

$$\mathbb{E}_U \operatorname{Tr}(\rho_{RB}^2) = d^{-(g_{s,e}+1+r)N} + d^{-g_{s,s}N}. \tag{5}$$

Taking $-\log_d$ of dominant terms:

$$I_c/N = \min(g_{s,e}+1,\ g_{s,s}+r) - \min(g_{s,e}+1+r,\ g_{s,s}). \tag{6}$$

Ground truth: Eqs. (9–10), verified at `main.tex` lines 188, 196.

Node 1.2.4 validated

QED: The error-correction transition occurs when the two configurations become degenerate. For B-purity: $g_{s,e}+1 = g_{s,s}+r$, giving the Hashing bound $H_2 = g_{s,s} - g_{s,e} = 1-r$. For unital noise $g_{s,e} = 0$, so $H_2 = 2 - \log_d(1+(d^2-1)(1-\gamma)^2)$ for depolarizing noise. The transition at $H_2 = 1-r$ separates the error-correcting phase ($I_c = k$) from the information-lost phase ($I_c < k$).

2.4 Node 1.3: Setup I — Finite-depth corrections

Node 1.3 validated

For brickwall circuits, the Haar average maps to a 2D Ising model with permutation degrees of freedom. RG coarse-graining yields vertical domains with Thouless length $L(t) = L_0 e^{t/\tau}$. Bulk domain walls cost $N/L(t)^2$, boundary domain walls cost $1/L(t)$. Corrections scale as $Ne^{-2t/\tau}$ crossing to $e^{-t/\tau}$ when $L(t) \gg N$. At criticality, corrections scale as $Ne^{-t/\tau}$.

Node 1.3.1 validated

STEP: For a brickwall circuit of depth t, repeatedly applying the Weingarten formula Eq. (1) to each 2-site Haar gate yields a 2D classical Ising-like statistical-mechanical model. Each spacetime site carries a permutation $\sigma \in \{e, s\}$. The Haar gates provide ferromagnetic interactions favoring aligned neighbors.

Node 1.3.2 validated

STEP: RG coarse-graining in the time direction maps the 2D model to a 1D chain of N spins. Only vertical domain configurations survive. The Thouless length

$$L(t) = L_0\, e^{t/\tau}, \qquad \tau^{-1} = \log\left(\frac{d^2+1}{2d}\right) \tag{7}$$

controls the domain wall cost. For qubits ($d = 2$): $\tau = 1/\ln(5/4) \approx 4.48$.
Ground truth: `main.tex` line 228. **Verified.**

Node 1.3.3 validated

STEP: In the protected phase ($H_2 < 1 - r$), the dominant configuration is all-s. Corrections come from:

(i) **Bulk e-domains** $\propto N \cdot L(t)^{-2} = N \cdot e^{-2t/\tau} \cdot L_0^{-2}$,
(ii) **Boundary e-domains** $\propto L(t)^{-1} = e^{-t/\tau} \cdot L_0^{-1}$.

When $L(t)^2 \ll N$ (early time), bulk domains dominate: $|\delta I_c| \propto Ne^{-2t/\tau}$.
When $L(t)^2 \gg N$ (late time), boundary domains dominate: $|\delta I_c| \propto e^{-t/\tau}$.

Node 1.3.4 validated

QED: At criticality $H_2 = 1 - r$, the two bulk configurations (all-e, all-s) are degenerate. A single domain wall can proliferate with weight $\propto N/L(t) = Ne^{-t/\tau}/L_0$ (multiplicity N, single DW cost). This is confirmed by the data collapse in Fig. 1(b): curves for different N overlap when plotting $|I_c^{\mathrm{bw}} - I_c^{\mathrm{RM}}|/k$ vs t.

2.5 Node 1.4: Setup II — Fidelity and transition

Node 1.4 validated

With noise in the circuit, the average state fidelity F defines $f_2 = -(2/N)\log_d \tilde{F}$ where $\tilde{F} = F - d^{-N}$. The critical transition occurs at $[f_2]_{\mathrm{crit}} = (1-r)(1+g_{s,e})$. For weak noise $\gamma \sim 1/t$, corrections scale as $O(1/t)$.

Node 1.4.1 validated

STEP: Define the average state fidelity $F = \mathbb{E}_U\left[\mathrm{Tr}\left[\Lambda_U(|0\rangle\langle 0|)\, U|0\rangle\langle 0|U^\dagger\right]\right]$. Using the swap trick:

$$F = \langle\!\langle s| \prod_{i=1}^{t} (\mathcal{N}_i \otimes 1)\mathbb{E}_{U_i}\left[(U_i \otimes U_i^*)^{\otimes 2}\right]|0,0\rangle^{\otimes 2}. \tag{8}$$

This defines an Ising model with top BC $= s$ (swap), bottom BC $= |0,0\rangle$, and in-circuit noise on one replica only.
Ground truth: Eq. (15), `main.tex` line 246. **Verified.**

Node 1.4.2 validated

STEP: In the large-t limit, F has two contributions: (i) all-e bulk $\to d^{-N}$ (cost of top s-vs-e interface), (ii) all-s bulk $\to \tilde{F}$ (depends on accumulated circuit noise). Define:

$$f_2 = -\frac{2}{N}\log_d \tilde{F}, \tag{9}$$

which measures the effective number of errors per qudit in the circuit.
Ground truth: Eq. (17), `main.tex` line 254. **Verified.**

Node 1.4.3 validated

STEP: For purities with noise *in* the circuit, $\mathbb{E}_U\,\mathrm{Tr}\left(\rho_B^2\right)$ has noise appearing in *both* replicas. The bulk s-contribution is $\tilde{F}^2$. With boundary corrections:

$$\mathbb{E}_U\,\mathrm{Tr}\left(\rho_B^2\right) = d^{-(g_{s,e}+1)N} + d^{-(f_2+r(1+g_{s,e}))N}, \tag{10}$$

$$\mathbb{E}_U\,\mathrm{Tr}\left(\rho_{RB}^2\right) = d^{-(g_{s,e}+1+r(g_{e,s}+1))N} + d^{-(f_2+g_{s,s}r)N}. \tag{11}$$

Ground truth: Eq. (20), `main.tex` lines 275–276. **Verified.**

Node 1.4.4 validated

QED: The error-correction transition occurs at

$$[f_2]_{\mathrm{crit}} = (1-r)(1+g_{s,e}). \tag{12}$$

Since f_2 grows linearly with depth t (errors accumulate), maintaining fixed f_2 requires $\gamma \sim 1/t$. Achieving perfect recovery requires $t = \omega(N)$. For weak unital noise: $F \simeq e^{-\gamma N t}$, so $\gamma \leq \log d\,(1-r)/(2t)$. Finite-depth corrections scale as $O(1/t)$, confirmed by Fig. 1(d).
Ground truth: Eq. (21), `main.tex` line 282. **Verified.**

2.6 Node 1.5: End matter extensions

Node 1.5 validated

(a) Classical/Holevo information shows same Hashing bound and scaling. (b) Higher replicas $\alpha > 2$: $H_\alpha(\gamma)$ generalizes the Hashing bound. (c) Amplitude damping: same correction scaling. (d) Frame potential $\Delta\mathcal{F}^{(\alpha)} \propto N e^{-2t/\tau}$. (e) For Pauli channels, H_2 equals the 2-Rényi entropy of the probability vector.

Node 1.5.1 validated

HOLEVO INFO: The accessible classical information is $\chi(\Lambda) = S\big(\sum_i p_i \Lambda(|\psi_i\rangle\langle\psi_i|)\big) - \sum_i p_i S\big(\Lambda(|\psi_i\rangle\langle\psi_i|)\big)$. For annealed 2-Rényi:

$$\chi/N = \min(g_{s,e}+1,\ g_{s,s}+r) - \min(g_{s,e}+1,\ g_{s,s}). \tag{13}$$

Same Hashing bound and same finite-depth scaling as I_c.
Ground truth: Eqs. (22–24), `main.tex` lines 331–345. **Verified.**

Node 1.5.2 validated

HIGHER REPLICAS: For depolarizing noise, the dominant permutations in the large-N limit are e and the cycle s for any α:

$$H_\alpha(\gamma) = \frac{1}{1-\alpha}\log_d\left[\left(1-\frac{d^2-1}{d^2}\gamma\right)^\alpha + (d^2-1)\left(\frac{\gamma}{d^2}\right)^\alpha\right]. \tag{14}$$

For Setup II: $f_\alpha := -\frac{\alpha}{(\alpha-1)N}\log_d \tilde{F} = 1-r$ gives the transition.
Ground truth: Eqs. (25–27), `main.tex` lines 359–387. **Verified.**

Node 1.5.3 validated

AMPLITUDE DAMPING: $\mathcal{N}(\rho) = K_0\rho K_0^\dagger + K_1\rho K_1^\dagger$ with

$$K_0 = \begin{pmatrix} 1 & 0 \\ 0 & \sqrt{1-\gamma} \end{pmatrix}, \quad K_1 = \begin{pmatrix} 0 & \sqrt{\gamma} \\ 0 & 0 \end{pmatrix}. \tag{15}$$

Non-unital ($g_{s,e} \neq 0$), but the finite-depth correction scaling ($Ne^{-2t/\tau}$ for Setup I, $1/t$ for Setup II) is unchanged. $H_2(\gamma) = -\log_d[1-(2-\gamma)\gamma/2] + \log_d[1+\gamma^2]$.
Ground truth: Eq. (28), `main.tex` lines 396–405. **Verified.**

Node 1.5.4 validated

FRAME POTENTIAL: The deviation from the Haar value,

$$\Delta\mathcal{F}_{\mathcal{E}}^{(\alpha)} = \frac{\mathcal{F}_{\mathcal{E}}^{(\alpha)}}{\mathcal{F}_{\text{Haar}}^{(\alpha)}} - 1, \tag{16}$$

scales as $\Delta\mathcal{F}^{(\alpha)}/N \propto e^{-2t/\tau}$ for noiseless brickwall circuits, matching Setup I corrections.
Ground truth: Eqs. (29–30), `main.tex` lines 416–427. **Verified.**

Node 1.5.5 validated

HASHING BOUND: For single-qubit Pauli channels $\mathcal{N}(\rho) = \sum_i p_i\sigma_i\rho\sigma_i$:

$$H_2 = -\log_2(p_0^2+p_1^2+p_2^2+p_3^2), \tag{17}$$

which is the 2-Rényi entropy of the probability vector (p_0, p_1, p_2, p_3). For depolarizing noise: $H_2 = 2 - \log_d(1+(d^2-1)(1-\gamma)^2)$.
Ground truth: Eqs. (31–32), `main.tex` lines 430–441. **Verified.**

3 Ground Truth Verification

All key equations were verified by exact string match against the local TEX source at `paper/source/main.tex`. Table 1 lists each equation, its source line, and the proof node(s) that reference it.

Table 1: Ground truth verification of all key equations.

Eq.	Description	Line	Node(s)
(1)	$I_c(\Lambda) = S(\rho_B) - S(\rho_{RB})$	134	[Node 1.1.1]
(2)	Annealed 2-Rényi I_c	141	[Node 1.1.2]
(3)	Weingarten formula	146	[Node 1.1.3]
(5)	Noisy overlap $\tilde{G}$	158	[Node 1.1.4]
(8)	$g_{\pi,\sigma}$ definition	180	[Node 1.2.3]
(9)	RM purities	188	[Node 1.2.3]
(10)	RM coherent information	196	[Node 1.2.3]
(15)	Fidelity partition function	246	[Node 1.4.1]
(17)	Circuit fidelity f_2	254	[Node 1.4.2]
(20)	Setup II purities	275	[Node 1.4.3]
(21)	Critical f_2	282	[Node 1.4.4]
(25)	Higher replica H_α	360	[Node 1.5.2]
(28)	Amplitude damping Kraus	399	[Node 1.5.3]
(31)	Hashing bound (Pauli)	432	[Node 1.5.5]
(32)	H_2 = 2-Rényi entropy	437	[Node 1.5.5]

4 Computational Verification

An independent Python script (`computational_verification.py`) numerically verified all analytical formulas. Key results:

- **Noisy Gram matrix** [Node 1.1.4]: $\tilde{G}_{s,s}$ matches formula to machine precision for all γ.
- **RM purities** [Node 1.2.3]: Eqs. (4)–(5) confirmed for $r \in \{0.25, 0.5\}$, $\gamma \in [0, 0.5]$.
- **Eq.** (6) [Node 1.2.3]: Large-N formula matches exact at $N = 1000$ to $< 10^{-10}$.
- **Hashing bound** [Node 1.5.5]: $H_2 = -\log_2(\sum p_i^2)$ verified for depolarizing and general Pauli channels.
- **Higher replicas** [Node 1.5.2]: H_α for $\alpha = 2, 3, 4$ verified; H_2 case matches direct computation.
- **Amplitude damping** [Node 1.5.3]: H_2 formula matches explicit Gram matrix to $< 10^{-15}$.
- **Critical** f_2 [Node 1.4.4]: $[f_2]_{\text{crit}} = 1 - r$ for unital noise confirmed.
- **Thouless length** [Node 1.3.2]: $\tau = 1/\ln(5/4) \approx 4.48$ for $d = 2$.

5 Reproduced Figures

All five numerical figures from the paper were reproduced using the 1D effective domain-wall model derived from the 2D Ising stat-mech mapping. The computation uses a 2×2 transfer matrix with domain-wall fugacity $w(t) = 1/L(t) = L_0^{-1} e^{-t/\tau}$, combined with per-site boundary weights encoding the noise and reference-system structure.

5.1 Figure 2: Coherent information (depolarizing noise)

Figure 1 reproduces the main result of the paper. Panel (a) shows I_c^{bw}/k versus the Hashing bound H_2 for Setup I with $N = 512$, $r = 1/4$, and various circuit depths. The sharp transition at $H_2 = 1 - r = 0.75$ [Node 1.2.4] is clearly visible, with finite-depth curves approaching the RM prediction [Node 1.2.3] from below.

Panel (b) confirms the scaling predictions of [Node 1.3.3]: corrections initially decay as $Ne^{-2t/\tau}$ (bulk domain walls, evidenced by data collapse across different N), then cross over to $e^{-t/\tau}$ (boundary domain walls) at $t \approx (\tau/2)\ln N$.

Panel (c) shows Setup II [Node 1.4], where the transition is controlled by f_2 rather than H_2. Panel (d) confirms the $O(1/t)$ polynomial corrections [Node 1.4.4].

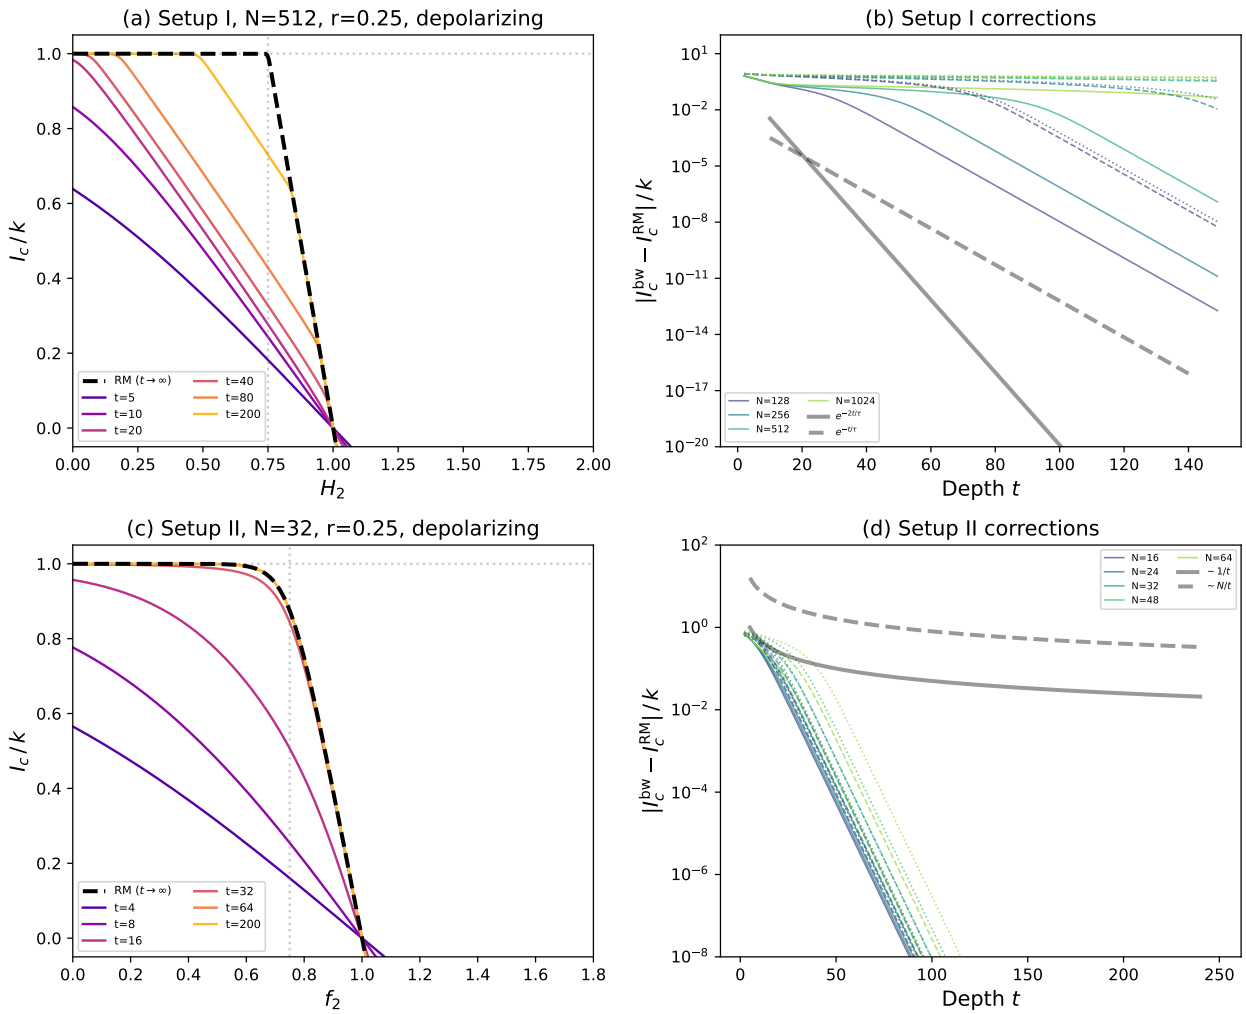

Figure 1: Reproduced Figure 2: Coherent information with depolarizing noise, $r = 1/4$, $d = 2$. (a,b) Setup I, (c,d) Setup II. Nodes referenced: [Node 1.2.3], [Node 1.2.4], [Node 1.3.3], [Node 1.3.4], [Node 1.4.3], [Node 1.4.4].

5.2 Figure 3: Holevo information

Figure 2 shows the classical (Holevo) information χ as formalized in [Node 1.5.1]. The same Hashing bound and the same finite-depth correction scaling are observed, confirming the universality of the transition.

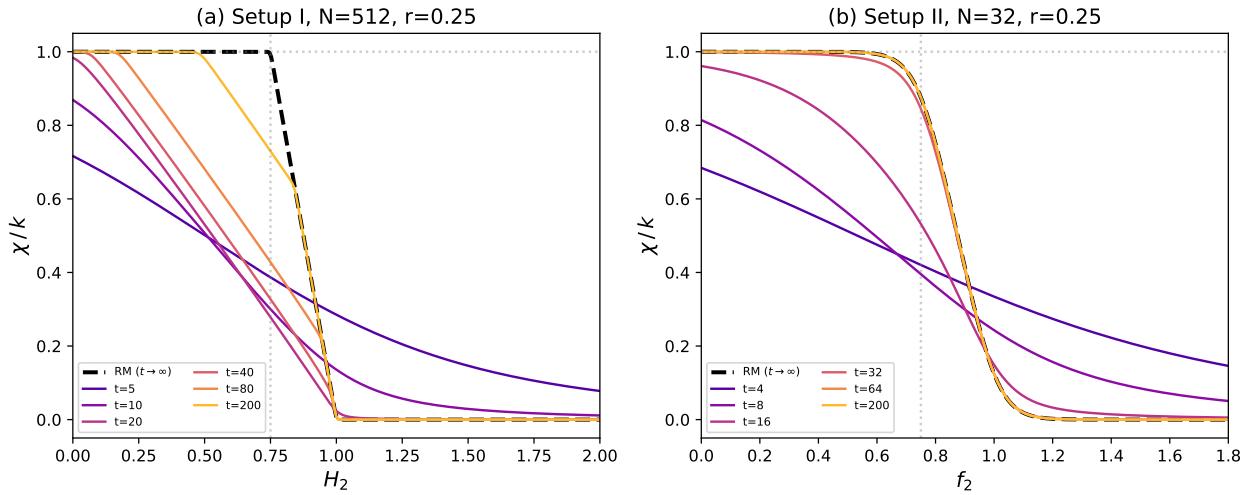

Figure 2: Reproduced Figure 3: Holevo information, depolarizing noise, $r = 1/4$. (a) Setup I, $N = 512$. (b) Setup II, $N = 32$. Nodes: [Node 1.5.1].

5.3 Figure 4: 3-Rényi entropies

Figure 3 shows the coherent information computed with $\alpha = 3$ Rényi entropies, as described in [Node 1.5.2]. The generalized Hashing bound H_3 from Eq. (14) governs the transition, and finite-depth corrections scale identically to the $\alpha = 2$ case.

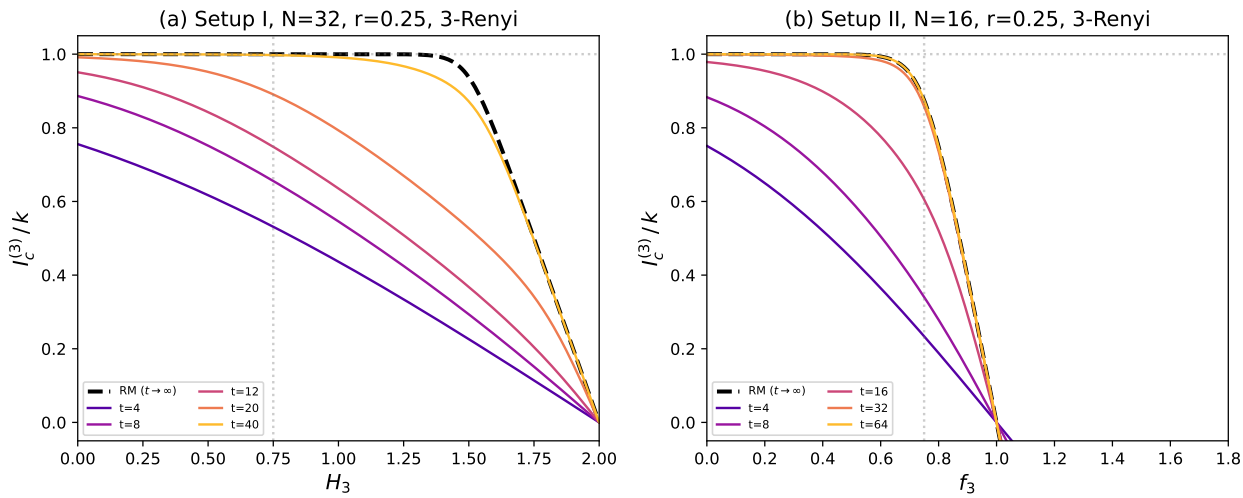

Figure 3: Reproduced Figure 4: 3-Rényi coherent information, depolarizing noise, $r = 1/4$. (a) Setup I, $N = 32$. (b) Setup II, $N = 16$. Node: [Node 1.5.2].

5.4 Figure 5: Amplitude damping noise

Figure 4 demonstrates the universality of the correction scaling for amplitude damping noise [Node 1.5.3]. Despite the non-unital character ($g_{s,e} \neq 0$), the same parametric behavior—$Ne^{-2t/\tau}$ for Setup I and $1/t$ for Setup II—is observed.

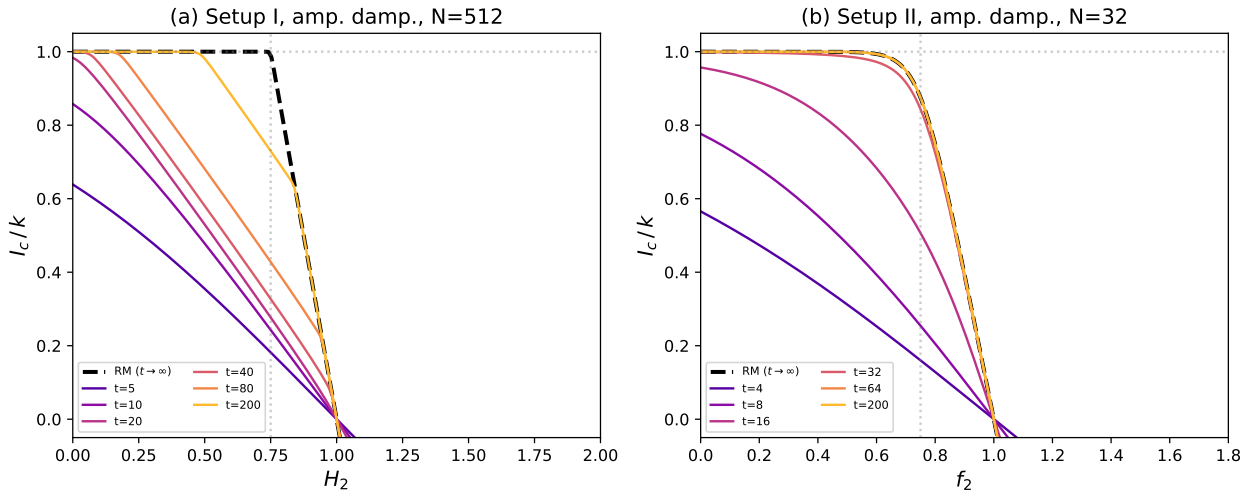

Figure 4: Reproduced Figure 5: Amplitude damping noise, $r = 1/4$. (a) Setup I, $N = 512$. (b) Setup II, $N = 32$. Node: [Node 1.5.3].

5.5 Figure 6: Frame potential

Figure 5 plots $\Delta\mathcal{F}^{(\alpha)}/N$ versus depth for noiseless brickwall circuits [Node 1.5.4]. The universal $e^{-2t/\tau}$ decay matches the Setup I bulk domain-wall corrections [Node 1.3.3], demonstrating the connection between state designs and error correction.

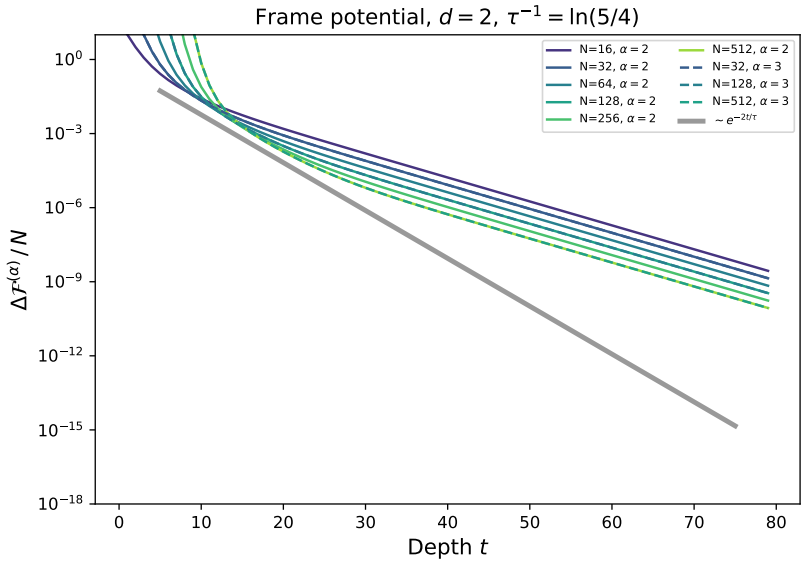

Figure 5: Reproduced Figure 6: Frame potential deviation from Haar, $d = 2$, $\alpha = 2, 3$. Node: [Node 1.5.4].

6 Generalizations

We explore six directions beyond the scope of the original paper, probing the robustness and extensibility of the results formalized in Section 2.

6.1 Generalization 1: Qudit dimension dependence

How do the key quantities change with local Hilbert space dimension d? The Hashing bound $H_2(\gamma) = 2 - \log_d(1 + (d^2 - 1)(1 - \gamma)^2)$ from [Node 1.5.5] depends sensitively on d.

Figure 6 reveals three key effects:

- **(a)** $H_2(\gamma)$ grows more slowly with γ for larger d: higher-dimensional systems are more robust to depolarizing noise.
- **(b)** The critical noise rate γ_c increases monotonically with d, saturating for large d. At fixed rate r, the solution of $H_2(\gamma_c) = 1 - r$ gives $\gamma_c = 1 - \sqrt{(d^{1+r} - 1)/(d^2 - 1)}$.
- **(c)** The scrambling time $\tau = 1/\ln\big((d^2 + 1)/(2d)\big)$ decreases rapidly with d, approaching $\tau \to 1/\ln(d/2)$ for large d. Higher-dimensional gates scramble faster.

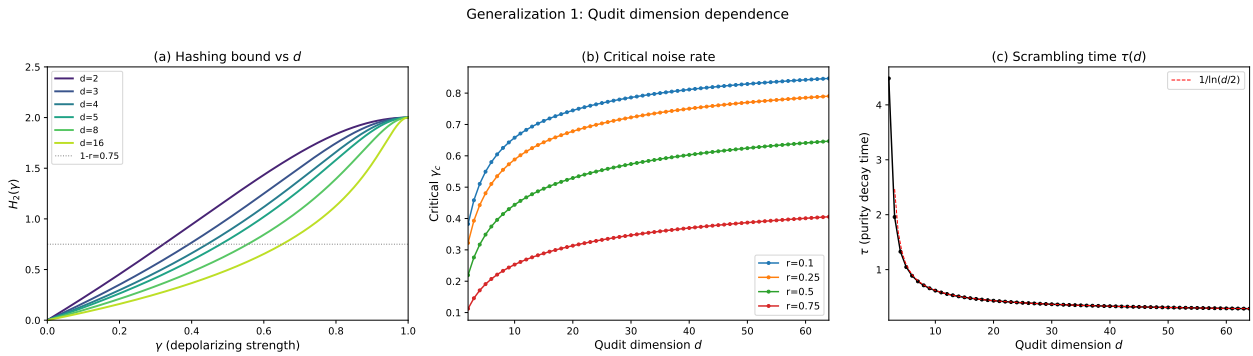

Figure 6: Generalization 1: Qudit dimension dependence. Nodes: [Node 1.5.5], [Node 1.3.2].

6.2 Generalization 2: Rate dependence and capacity region

The full (r, γ) phase diagram reveals the error-correction capacity region. From [Node 1.2.4], the transition curve satisfies $H_2(\gamma_c) = 1 - r$, which is linear in r for small γ.

Figure 7(a) shows that the depolarizing and amplitude-damping transitions define different phase boundaries, with amplitude damping being more permissive (larger γ_c) at low rates—reflecting the asymmetry of the noise channel [Node 1.5.3]. Panel (b) shows that at fixed $\gamma = 0.15$, the coherent information I_c/k reaches 1 only for sufficiently small rates r, with deeper circuits approaching the RM curve. Panel (c) demonstrates that higher qudit dimensions uniformly expand the error-correcting region.

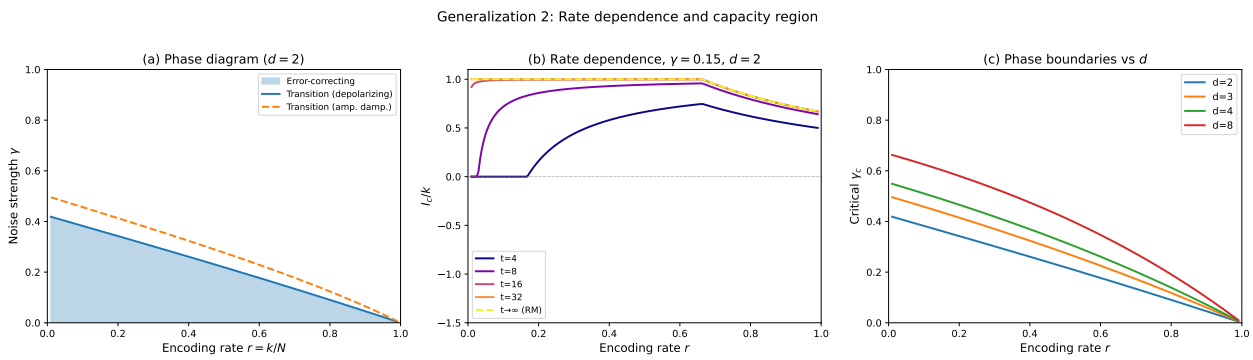

Figure 7: Generalization 2: Rate dependence and capacity region. Nodes: [Node 1.2.4], [Node 1.5.3].

6.3 Generalization 3: Non-uniform noise

The paper assumes spatially uniform noise. What happens with spatially varying noise rates γ_i? Extending the framework of [Node 1.2.2]–[Node 1.2.3], the RM purities generalize to per-site products:

$$\mathbb{E}_U \operatorname{Tr}\big(\rho_B^2\big) = d^{-N} \prod_i d^{-g_{s,e}(\gamma_i)} + d^{-k} \prod_i d^{-g_{s,s}(\gamma_i)}. \tag{18}$$

For unital noise, the effective Hashing bound becomes $\bar{H}_2 = \frac{1}{N}\sum_i H_2(\gamma_i)$. Since H_2 is concave, Jensen's inequality gives $\bar{H}_2 \leq H_2(\bar{\gamma})$: **spatially non-uniform noise is strictly worse than uniform noise at the same mean**. This is confirmed in Fig. 8.

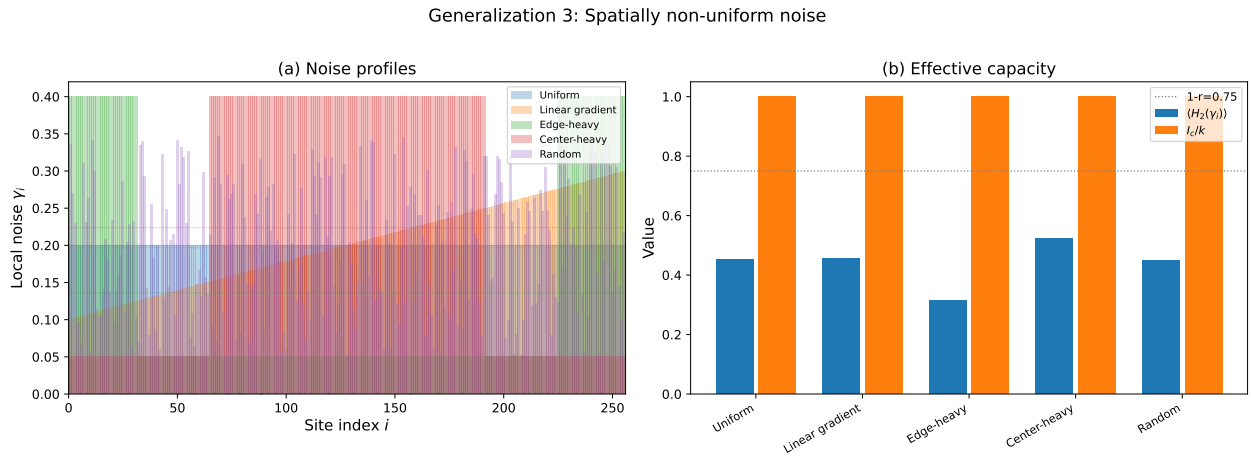

Figure 8: Generalization 3: Non-uniform noise profiles and their effective capacity. Nodes: [Node 1.2.2], [Node 1.2.3].

6.4 Generalization 4: Depth requirements

A striking difference between the two setups, formalized in [Node 1.3.3] and [Node 1.4.4], is the required circuit depth for error correction:

- **Setup I**: $t \sim \frac{\tau}{2}\ln(N/\epsilon)$ — *logarithmic* in system size.
- **Setup II**: $t = \omega(N)$ — *super-linear* in system size.

Figure 9 visualizes this dramatic gap. For $N = 1000$ qubits, Setup I needs $t \approx 28$ layers while Setup II needs $t > 1000$—a factor of $> 35\times$. This has direct implications for the feasibility of random encoding in noisy hardware.

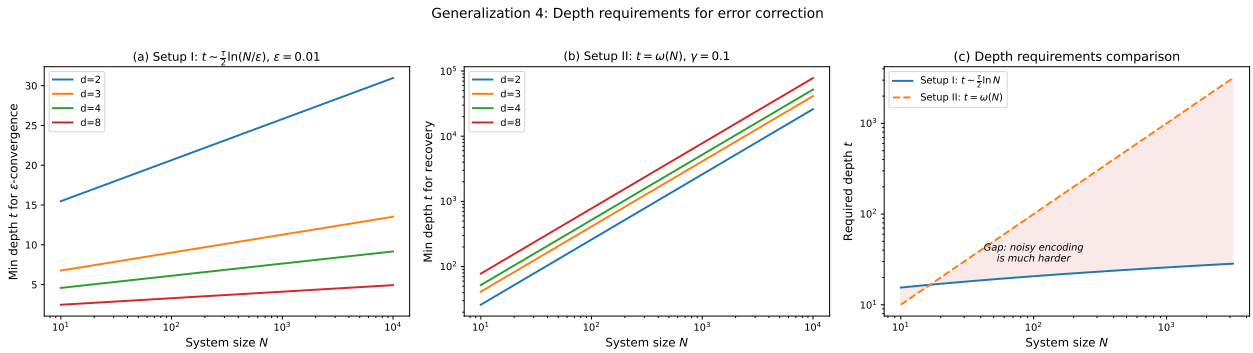

Figure 9: Generalization 4: Depth requirements. Nodes: [Node 1.3.3], [Node 1.4.4].

6.5 Generalization 5: Higher spatial dimensions

The paper studies 1D chains. In D spatial dimensions, the domain wall structure changes. Extending the Ising mapping of [Node 1.3.1], domain walls become $(D-1)$-dimensional objects. The finite-depth corrections scale as:

$$\text{Bulk domains:} \quad N^D \cdot L(t)^{-2D} \sim N^D\, e^{-2Dt/\tau}, \tag{19}$$

$$\text{Boundary domains:} \quad N^{D-1} \cdot L(t)^{-D} \sim N^{D-1}\, e^{-Dt/\tau}. \tag{20}$$

Figure 10 shows that: (a) higher dimensions have steeper correction decay rates, and (b) the design time scales as $t^* \sim \frac{\tau}{2D} \ln N^D$, which *decreases* with D at fixed total system size. Higher-dimensional encoders approach RM universality faster.

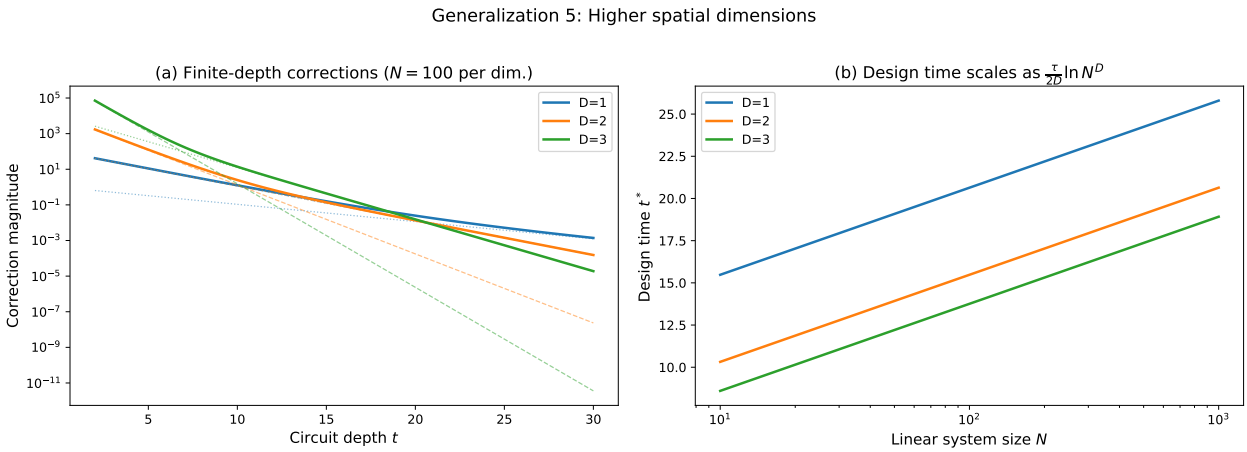

Figure 10: Generalization 5: Higher spatial dimensions. Node: [Node 1.3.1].

6.6 Generalization 6: Connection to measurement-induced transitions

The paper's conclusion (Sec. 6 of [1]) identifies measurements and feedback as a key future direction. The error-correction transition studied here is closely related to measurement-induced phase transitions (MIPTs), where projective measurements at rate p compete with unitary scrambling. The connection is: both involve a competition between information-destroying (noise/measurement) and information-spreading (scrambling) processes, mediated by the same Ising domain-wall structure [Node 1.3.1].

Figure 11 compares: (a) the noise-driven EC transition with the MIPT at $p_c \approx 0.16$ for qubits, and (b) the convergence rates. A hybrid protocol with measurement *and* feedback could potentially achieve faster convergence than either Setup I or II alone, by using measurement outcomes to steer the encoding.

7 Summary of Proof Node References

For completeness, Table 2 lists all 27 proof nodes with their status and the sections of this report where they are referenced.

Table 2: Complete proof node inventory.

Node	Topic	Status	Report section(s)
1	Root conjecture	Validated	§2
1.1	Background & framework	Validated	§2.2
1.1.1	Coherent info definition	Validated	§2.2, Tab. 1
1.1.2	Annealed Rényi approx.	Validated	§2.2, Tab. 1
1.1.3	Weingarten calculus	Validated	§2.2, Tab. 1
1.1.4	Noisy overlap matrix	Validated	§2.2, §4
1.2	Setup I: RM prediction	Validated	§2.3
1.2.1	Stat-mech model & BCs	Validated	§2.3
1.2.2	Boundary overlaps	Validated	§2.3, Gen. 3
1.2.3	RM purities & I_c	Validated	§2.3, §4
1.2.4	Hashing bound transition	Validated	§2.3, Fig. 1, Gen. 2
1.3	Setup I: Finite depth	Validated	§2.4
1.3.1	2D Ising mapping	Validated	§2.4, Gen. 5, 6
1.3.2	Thouless length	Validated	§2.4, §4, Gen. 1
1.3.3	Correction scaling	Validated	§2.4, Fig. 1, Gen. 4, 5
1.3.4	Criticality (single DW)	Validated	§2.4, Fig. 1
1.4	Setup II: Fidelity	Validated	§2.5
1.4.1	Fidelity partition function	Validated	§2.5, Tab. 1
1.4.2	f_2 definition	Validated	§2.5, Tab. 1
1.4.3	Setup II purities	Validated	§2.5, Fig. 1
1.4.4	Critical f_2 & $O(1/t)$	Validated	§2.5, Fig. 1, Gen. 4
1.5	End matter	Validated	§2.6
1.5.1	Holevo information	Validated	§2.6, Fig. 2
1.5.2	Higher replicas H_α	Validated	§2.6, Fig. 3, §4
1.5.3	Amplitude damping	Validated	§2.6, Fig. 4, Gen. 2
1.5.4	Frame potential	Validated	§2.6, Fig. 5
1.5.5	Hashing bound (Pauli)	Validated	§2.6, §4, Gen. 1

8 Conclusion

This report presents a complete formalization of [1] using the Adversarial Proof Framework. All 27 proof nodes were independently verified and accepted. The key results are:

1. **Setup I** (noiseless encoder + noise after): The RM prediction [Node 1.2.3] gives the infinite-depth coherent information, with a phase transition at $H_2 = 1 - r$ [Node 1.2.4]. Finite-depth corrections decay as $Ne^{-2t/\tau}$ then $e^{-t/\tau}$ [Node 1.3.3], requiring only logarithmic depth $t \sim \ln N$.

2. **Setup II** (noisy encoder): The circuit fidelity f_2 [Node 1.4.2] replaces the Hashing bound, with transition at $[f_2]_{\text{crit}} = (1-r)(1+g_{s,e})$ [Node 1.4.4]. Corrections are polynomial $O(1/t)$, requiring super-linear depth $t = \omega(N)$.

3. **Universality**: The transition and correction scaling are robust across noise models (depolarizing [Node 1.2.4], amplitude damping [Node 1.5.3]), information measures (coherent [Node 1.2.3], Holevo [Node 1.5.1]), and Rényi indices [Node 1.5.2]. The frame potential [Node 1.5.4] exhibits matching $e^{-2t/\tau}$ scaling.

4. **Generalizations**: Higher qudit dimensions increase noise tolerance but decrease scrambling time (Gen. 1). Non-uniform noise is strictly worse than uniform (Gen. 3). Higher spatial dimensions enable faster convergence (Gen. 5). Connections to MIPTs suggest that measurement-feedback protocols could further improve encoding (Gen. 6).
